1. $R_{DS(on)}$ is tested in the following way:

$$R_{\text{DS(on)}} = \frac{(V_{\text{CC}} - V_{\text{BOOT1}}) - (V_{\text{CC}} - V_{\text{BOOT2}})}{I_1(V_{\text{CC}}, V_{\text{BOOT1}}) - I_2(V_{\text{CC}}, V_{\text{BOOT2}})}$$

where I_1 is pin 8 current when $V_{\text{BOOT}} = V_{\text{BOOT1}}$, I_2 when $V_{\text{BOOT}} = V_{\text{BOOT2}}$.

Figure 3. Input/output timing diagram

5 Bootstrap driver

A bootstrap circuitry is needed to supply the high voltage section. This function is normally accomplished by a high voltage fast recovery diode ([Figure 4 a](#)). In the L6385E device a patented integrated structure replaces the external diode. It is realized by a high voltage DMOS, driven synchronously with the low-side driver (LVG), with a diode in series, as shown in [Figure 4 b](#). An internal charge pump ([Figure 4 b](#)) provides the DMOS driving voltage. The diode connected in series to the DMOS has been added to avoid undesirable turn-on.

C_{BOOT} selection and charging

To choose the proper C_{BOOT} value, the external MOSFET can be seen as an equivalent capacitor. This capacitor C_{EXT} is related to the MOSFET total gate charge:

Equation 1

$$C_{EXT} = \frac{Q_{gate}}{V_{gate}}$$

The ratio between the capacitors C_{EXT} and C_{BOOT} is proportional to the cyclical voltage loss. It has to be:

$$C_{BOOT} \gg C_{EXT}$$

E.g.: if Q_{gate} is 30nC and V_{gate} is 10V, C_{EXT} is 3nF. With C_{BOOT} = 100nF the drop would be 300 mV.

If HVG has to be supplied for a long time, the C_{BOOT} selection has to take into account also the leakage losses.

E.g.: HVG steady state consumption is lower than 200 μA, so if HVG T_{ON} is 5 ms, C_{BOOT} has to supply a maximum of 1 μC to C_{EXT}. This charge on a 1mF capacitor means a voltage drop of 1 V.

The internal bootstrap driver gives great advantages: the external fast recovery diode can be avoided (it usually has a great leakage current).

This structure can work only if V_{OUT} is close to GND (or lower) and in the meanwhile the LVG is on. The charging time (T_{charge}) of the C_{BOOT} is the time in which both conditions are fulfilled and it has to be long enough to charge the capacitor.

The bootstrap driver introduces a voltage drop due to the DMOS R_{DSON} (typical value: 125 Ω). At low frequency this drop can be neglected. Anyway increasing the frequency it must be taken in to account.

The following equation is useful to compute the drop on the bootstrap DMOS:

Equation 2

$$V_{drop} = I_{charge} R_{dson} \rightarrow V_{drop} = \frac{Q_{gate}}{T_{charge}} R_{dson}$$

where Q_{gate} is the gate charge of the external power MOSFET, R_{dson} is the on resistance of the bootstrap DMOS, and T_{charge} is the charging time of the bootstrap capacitor.

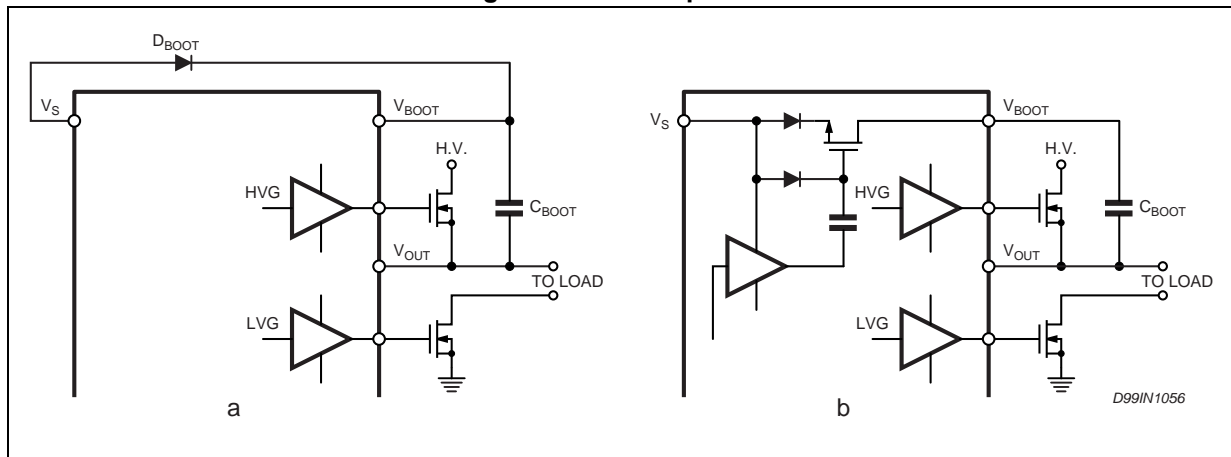

For example: using a power MOSFET with a total gate charge of 30 nC the drop on the bootstrap DMOS is about 1 V, if the T_{charge} is 5 ms. In fact:

Equation 3

$$V_{\text{drop}} = \frac{30\text{nC}}{5\mu\text{s}} \cdot 125\Omega \sim 0.8\text{V}$$

V_{drop} has to be taken into account when the voltage drop on C_{BOOT} is calculated: if this drop is too high, or the circuit topology doesn't allow a sufficient charging time, an external diode can be used.
