

## SELECTION GUIDE

| Part Number  | Packing              |
|--------------|----------------------|
| A3942KLGTR-T | 4000 pieces per reel |

## ABSOLUTE MAXIMUM RATINGS\*

| Characteristic                          | Symbol              | Notes                  | Rating  | Units |
|---|---------------------|------------------------|---|-------|
| V <sub>BB</sub> , CP1, CP3 Pins Voltage |                     |                        | −0.3 to 60  | V     |
| Dx (Drain Detect) Pins Voltage          | V <sub>Dx</sub>     |                        | V <sub>BB</sub> − 6 V<br>to V <sub>BB</sub> + 0.5 V | V     |
| Sx (Output Source) Pins Voltage         | V <sub>Sx</sub>     |                        | −10 to 60   | V     |
| VCP, CP2, CP4, Gx Pins Voltage          |                     |                        | −0.3 to 74  | V     |
| All Other Pins                          |                     |                        | −0.3 to 7   | V     |
| Operating Ambient Temperature           | T <sub>A</sub>      | Range K                | −40 to 125  | °C    |
| Maximum Junction Temperature            | T <sub>J(max)</sub> |                        | 150   | °C    |
| Storage Temperature                     | T <sub>stg</sub>    |                        | −55 to 150  | °C    |
| ESD Rating, Human Body Model            |                     | AEC-Q100-002, all pins | 2500  | V     |
| ESD Rating, Charged Device Model        |                     | AEC-Q100-011, all pins | 1050  | V     |

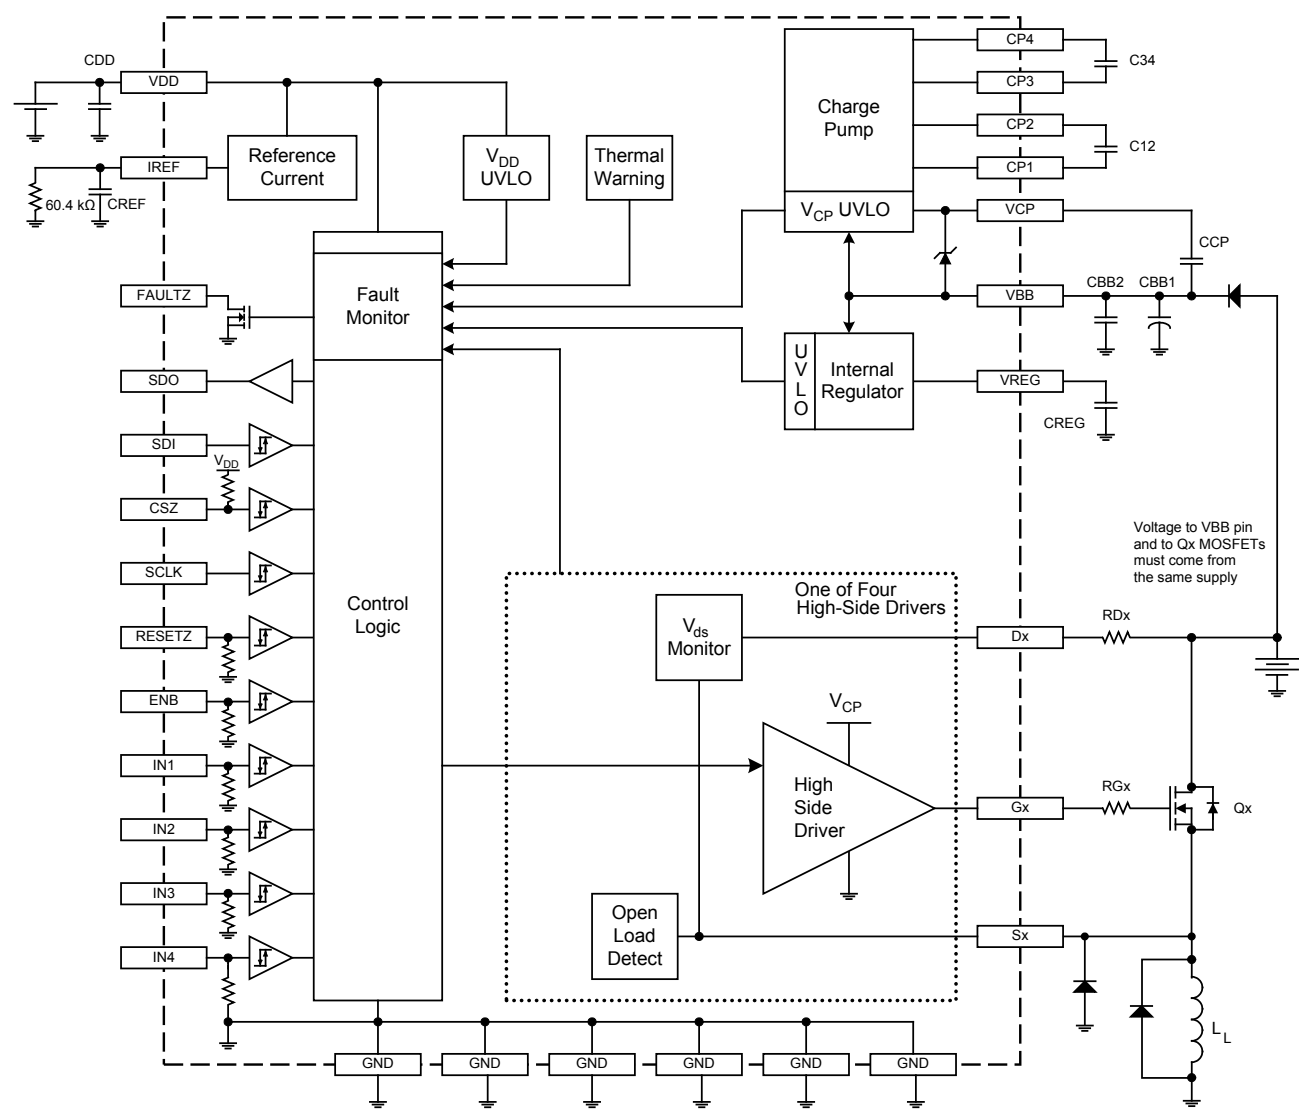

\*With respect to ground at T<sub>A</sub> = 25°C. Exceeding maximum ratings may cause permanent damage. Correct operation is not guaranteed when absolute maximum conditions are applied.

## THERMAL CHARACTERISTICS

| Characteristic                                  | Symbol           | Test Conditions*  | Rating | Units |
|---|------------------|---|--------|-------|
| Package Thermal Resistance, Junction to Ambient | R <sub>θJA</sub> | 4-layer PCB based on JEDEC standard, with no thermal vias | 47     | °C/W  |

\*For additional information, refer to the Allegro website.

Functional Block Diagram

| Name     | Suitable Characteristics              | Representative Device |
|----------|---------------------------------------|-----------------------|
| C12, C34 | 0.33 μF or 0.47 μF, 25 V, X7R ceramic |                       |
| CBB1     | 47 μF, 63 V, electrolytic             | EGXE630ELL470MJC5S    |
| CBB2     | 0.22 μF, 100 V, X7R ceramic           |                       |
| CCP      | 1 μF, 16V, X7R ceramic                |                       |
| CDD      | 0.47 μF, 16 V, X7R ceramic            |                       |
| CREF     | 47 pF, 16 V, X7R ceramic              |                       |
| CREG     | 0.22 μF, 16 V, X7R ceramic            |                       |

**ELECTRICAL CHARACTERISTICS** Valid at  $-40^{\circ}\text{C} \leq T_J \leq 150^{\circ}\text{C}$ ,  $C_{12} = C_{34} = 0.47\ \mu\text{F}$ ,  $\text{CCP} = 1\ \mu\text{F}$ ,  $R_{\text{REF}} = 60.4\ \text{k}\Omega$ , and  $V_{\text{BB}}$  within limits, unless otherwise noted

<sup>1</sup>For input and output current specifications, negative current is defined as coming out of (sourcing) the specified device pin.

<sup>2</sup>For  $I_{\text{G(HI)}}$ ,  $V_{\text{CP}}$  relative to  $V_{\text{BB}}$ .

<sup>3</sup>Minimum values of  $V_{\text{Dx}}$  are specified only to avoid short-to-battery nuisance faults. For more information, refer to the Open Load Fault Level topic in the Applications Information section.

<sup>4</sup>Minimum and maximum not tested; guaranteed by design.

## SERIAL PORT REGISTERS DESCRIPTION

There are two 8-bit registers served by the serial port, the Input register and the Output Fault register. The structure of the registers is shown in the table at the bottom of this page. The function of each bit in the registers is described in this section.

## INPUT REGISTER

**D0 Gate On/Off Bit** This bit is used to control the gate drive output. It is logically ORed with the signal on the discrete input pin, INx, corresponding to each of the four channels, according to the following table:

| ORed Settings |         | Result on<br>Gx Pin |
|---------------|---------|---------------------|
| Bit D0        | Pin INx |                     |
| 0             | 0       | Off                 |
| 0             | 1       | On                  |
| 1             | 0       | On                  |
| 1             | 1       | On                  |

**D1, D2 Short-to-Ground (STG) Turn-On Blank Time**

**MSB and LSB Bits** The blank time,  $t_{on(xx)}$ , delay allows switching transients to settle before the A3942 STG function checks for a short. For each individual channel, the combination of these bits sets the wait time for the  $V_{DS}$  monitor, according to the following table:

| D2 | D1 | $t_{ON}$ Selected |
|----|----|-------------------|
| 0  | 0  | $t_{ON(00)}$ *    |
| 0  | 1  | $t_{ON(01)}$      |
| 1  | 0  | $t_{ON(10)}$      |
| 1  | 1  | $t_{ON(11)}$      |

\*default state at device power-on

**D3 Clear Faults Bit** This bit is used to clear a latched fault. After the fault is cleared, the gate output can again follow the input logic to determine if the fault is still present. Faults are cleared on a channel specific basis.

**D4 Mask Off-State Faults Bit** [See asterisks (\*) in the table below.] When the application requires that Short-to-Battery (STB) and Open Load (OL) faults be checked primarily before output is enabled for the first time, this bit can be used to allow STB and Open Load faults to be ignored during normal operation (Short-to-Ground faults can not be masked). This bit is applied on a channel-specific basis, according to the following table:

| D4 Setting | Handling of<br>Off-State Faults |
|------------|---------------------------------|
| 0          | Registered                      |
| 1          | Ignored                         |

**Serial Port Bit Definition** All bits active high, except WriteZ

| Register     | Bits        |             |                   |                           |                 |                     |                    |             |
|--------------|-------------|-------------|-------------------|---------------------------|-----------------|---------------------|--------------------|-------------|
|              | D7          | D6          | D5                | D4                        | D3              | D2                  | D1                 | D0          |
| Input        | Address MSB | Address LSB | Input Read Enable | Mask Off-State Faults (*) | Clear Faults    | STG Blank Time MSB  | STG Blank Time LSB | Gate On/Off |
| Output Fault | Address MSB | Address LSB | WriteZ            | Charge Pump UVLO          | Thermal Warning | Open Load Fault (*) | STB Fault (*)      | STG Fault   |

**D5 Read Enable Bit** This bit enables or disables reading on the serial inputs, according to the following table:

| D5 Setting | Handling of Serial Input |
|------------|--------------------------|
| 0          | Ignored                  |
| 1          | Registered               |

**D6, D7 Address MSB and LSB Bits (Input and Output Fault registers)** For channel-specific bits, these bits are used to specify which channel is indicated. The channel-specific bits are:

| Register | Channel-Specific Bits |
|----------|-----------------------|
| Input    | D0, D1, D2, D3, D4    |
| Output   | D0, D1, D2            |

These bits determine the channel, according to the following table:

| D7 | D6 | Channel Selected |
|----|----|------------------|
| 0  | 0  | 1                |
| 0  | 1  | 2                |
| 1  | 0  | 3                |
| 1  | 1  | 4                |

## OUTPUT FAULT REGISTER

**D0 Short-to-Ground (STG) Fault Bit** The voltage from drain to source for each MOSFET is monitored. An internal current source sinks  $I_{Dx}$  from the Dx pins to set the  $V_{DS}$  threshold for each channel, the level at which an STG fault condition is evaluated.

The A3942 enables monitoring for an STG fault after the MOSFET is turned on and the turn-on blank time,  $t_{ON}$ , expires. (The MOSFET is turned on via the Input register D0 bit, ORED with the INx discrete input pin for the channel of the MOSFET, and  $t_{ON}$  is set by Input register D1 and D2 bits). If the MOSFET gate-to-source voltage exceeds the  $V_{DS}$  threshold, then an STG fault will be registered for that channel, the MOSFET gate will be discharged, and the FAULTZ pin will be set low (active).

An STG fault is latched until cleared (using the Input register D3 bit). In the meantime, the other channels can continue to operate normally.

**D1 Short to Battery (STB) Fault Bit** When a channel gate drive output turns off, by setting it off with the input pin or through SPI, or due to a latched fault, STB fault detection for that

channel is blanked for  $t_{OFF}$ . Subsequently, if the Sx pin voltage exceeds the  $V_{DS}$  threshold voltage for that channel, an STB fault is latched. The gate drive output for that channel is disabled until the fault is either cleared (via the Input register D3 bit) or the off-state fault diagnostics are masked (via the Input register D4 bit).

Because the output is disabled, there is no active pull-down during an STB event. Note that, in general, when the voltage on SX is high enough to trip the STB comparator, it also trips the OL comparator, and both the STB and the OL faults are latched.

**D2 Open Load (OL) Fault Bit** When a gate drive output channel turns off by setting it off with the input pin or through SPI, or due to a latched fault, the OL fault for that channel is blanked for  $t_{OFF}$ . A small bias current,  $I_{OL}$ , is sourced to the Sx pin of the channel where it divides between RSx and the load. If the load is open, the Sx voltage will rise above the OL fault detection threshold. In that case, the output is disabled until the fault is cleared (via the Input register D3 bit) or the off-state fault diagnostics are masked (via the Input register D4 bit).

After the  $t_{ON}$  and  $t_{OFF}$  blanking expires, all STG, STB, and OL conditions must be present for longer than the Fault Filter Time,  $t_{FF}$ , before the fault can be registered.

**D3 Thermal Warning Bit** A die temperature monitor is integrated on the A3942 chip. If the die temperature approaches the maximum allowable level, a thermal warning signal will be triggered.

Note that this fault sets the FAULTZ pin low (active), but does not disable the outputs or operation of the chip.

**D4 Charge Pump UVLO Bit** The charge pump must maintain a voltage guard band above  $V_{BB}$ , in order to charge the gates when commanded to turn on the MOSFETs. If an undervoltage (UVLO) condition is detected on the charge pump, the FAULTZ pin will be set low (active), and all outputs will be disabled.

**D5 WriteZ (Not Write) Bit** In a written byte, D5 = 0.

**D6, D7 Address Bits** See description, above.

## PIN DESCRIPTIONS

In this section, the functions of the individual terminals of the A3942 are described.

**VBB Supply Voltage (Power)** The A3942 is fully operational over the specified range of  $V_{BB}$ . The external MOSFETs must be supplied by the same voltage source as the A3942. A bypass capacitor should be placed as close as practicable to the A3942.

**VDD Supply Voltage (Logic)** Logic voltage must be supplied to the A3942. The wide allowable range of input voltages allows both 3.3 V and 5 V supplies. A bypass capacitor should be placed as close as practicable to the A3942.

**VCP Charge Pump** The integrated charge pump is used to generate a supply above  $V_{BB}$  to drive the gates of the external power MOSFETs. This tripler keeps the part functional over a wide range of  $V_{BB}$ .

**CP1 through CP4 Charge Pump Capacitor Connections** These are the connections for the two external capacitors that level-shift the charge up to  $V_{CP}$ .

**VREG Internal Linear Voltage Regulator** This provides a connection for an external capacitor that sets the regulation value for voltage supplied to internal logic circuits.

**IN1 through IN4 Discrete Inputs** For each output channel, the gate pin,  $G_x$ , sources voltage when the corresponding  $IN_x$  pin is set high.  $G_x$  sinks voltage to ground when the corresponding  $IN_x$  pin is set low. The  $IN_x$  setting is logically ORed with the Gate On/Off bit (Input register bit D0) for the respective output.

**D1 through D4 Output Drains** For each output channel, the voltage on the corresponding  $D_x$  pin is used to evaluate STB and STG fault conditions. The A3942 compares the  $D_x$  voltage level to the  $V_{DS}$  threshold of the MOSFET to determine if a fault condition exists. The trip voltage level is set by selecting an appropriate value for the resistor,  $RD_x$ , connected to the corresponding current sink. Because both the  $D_x$  pins and  $RD_x$  are high impedance, each  $RD_x$  must be placed as close to the corresponding A3942  $D_x$  pin as practicable.

**G1 through G4 Output Gates** These pins drive the gates of the high-side external MOSFETs. They source voltage from VCP and sink to GND. The corresponding external gate resistors,  $RG_x$ , should be  $\geq 2 \text{ k}\Omega$  for consistent switching times between A3942s when applicable (see  $I_{G(HI)}$  and  $I_{G(LO)}$  in the Electrical Characteristics table).

If negative voltages are applied,  $G_x$  is clamped to GND by internal diodes. Back-to-back Zener diodes are internally connected between  $G_x$  and  $S_x$ .

**Sx Output Sources** These are used to measure the source terminal of the external MOSFET. The pins may be tied directly to the MOSFET. Although the  $S_x$  pins can survive large negative transients, it is recommended to connect a clamp diode between the  $S_x$  pin and ground to limit any negative transients at the  $S_x$

pin when a load is switched off. This helps to avoid false fault detection caused by transient noise coupling into adjacent channels which may not be switching and therefore have no fault blanking during the transient. This is especially recommended when there is significant wiring between the load and the  $S_x$  pin even if the load incorporates a recirculation diode.

**RESETZ Master Reset and Sleep Mode** Pulsing this pin low clears all latched faults in the channel-specific fault registers. It also clears the serial port registers (they return to their default values). When RESETZ is held low long enough ( $t > t_{SLEEP}$ ) the A3942 goes to sleep, as described in the Sleep topic in the Functional Description section.

**ENB Enable** Set low to actively pull low all outputs.

**FAULTZ Fault** Active low open drain output. Signals a fault. Allows parallel connection with FAULTZ signals from other devices when required.

**SCLK SPI Clock** See Serial Port Operation topic in Functional Description section.

**CSZ SPI Chip Select input.**

**SDO SPI Data Output connection.**

**SDI SPI Data Input connection.**

**IREF Current Reference** Defines the current used as a reference to set gate drive currents, diagnostic currents and internal timers. A resistor,  $R_{REF}$ , connected between the IREF pin and the adjacent GND pin is selected to set the reference current to  $20\mu\text{A}$ . The IREF pin is a voltage source at a voltage,  $V_{REF}$ , of typically 1.2V. The resistor required is therefore  $60.4\text{k}\Omega$ , which is the standard resistor value that provides a typical current closest to the  $20\mu\text{A}$  target. Any variation in  $R_{REF}$  will affect the internal settings as described in the section below on  $R_{REF}$  selection. Being a high impedance node, the IREF pin is susceptible to external sources of noise and transients and should be decoupled with a capacitor across  $R_{REF}$  between the IREF pin and the adjacent GND pin. The capacitor value should be less than  $100\text{pF}$  to avoid any delay when power is first applied to the A3942 or when coming out of sleep mode. When controlling large load currents a larger capacitor may be required to suppress any transient noise. At power-on or when coming out of sleep mode this capacitor will be charged at typically  $240\mu\text{A}$  until it reaches  $V_{REF}$ . The time taken to charge the capacitor will be approximately:

$$t_{CHARGE} = 5 \times C$$

where  $t_{CHARGE}$  is in  $\mu\text{s}$  and  $C$  is the capacitor value in nF. At least

twice this time should be allowed, after power-on or after coming out of sleep mode, before the A3942 is used to switch any loads.

**GND Ground** All GND pins are internally fused to the metal die pad to which the chip is soldered. This allows for high thermal conductance through the GND pins. Connecting to these pins to a PCB ground plane improves thermal performance.

## FUNCTIONAL DESCRIPTION

**Power On** When power is applied to either VDD or VBB, the Output Fault register is initially loaded with default values, all zeros (0). However, as individual internal circuits are initially powered on, they may latch spurious faults in the fault registers for each channel. Therefore, before operating the A3942 all fault registers must be cleared by pulsing the RESETZ pin.

**Sleep Mode** This mode disables various internal circuits including the charge pump, VREG, and the logic circuits. The serial port also is disabled. All Input and Output Fault register bits are cleared.

To leave sleep mode, pull RESETZ high and then allow a delay for the charge pump to stabilize. Before sending commands, clear any spurious faults as described in the Power On topic.

**Faults** Faults are categorized either as *system faults* or *load faults*. All faults are ORed to the FAULTZ pin.

System faults are VREG UVLO, CP UVLO, VDD UVLO, and Thermal Warning. They are not latched in the channel-specific self-protection circuit fault registers, however, the flags in the Output Fault register bits D3, D4, and D5, are latched. If the fault condition is resolved, these flags are latched until they are read, at which time they are cleared.

Load faults are OL, STB, and STG. They are latched into the channel-specific self-protection circuit fault registers, and shifted into Output Fault register bits D0, D1, and D2 when called. Thus, load faults may be masked or cleared on a channel-specific basis.

## SERIAL PORT OPERATION

The serial port is compatible with the full duplex Serial Peripheral Interface (SPI) conventions. The inputs to the SPI port are logically ORed with the discrete input pins, INx, settings. This allows independent operation using only the discrete inputs, only the serial inputs, or both. Timing is clocked by an on-board 4 MHz oscillator.

When a Chip Select event occurs, the Output Fault register loads one eight-bit byte into the shift register, and the byte is then shifted out through the SDO pin. Simultaneously, bits at the SDI

pin are shifted into the shift register (full duplex). At the end of a Chip Select event, the shift register contents are latched into the Input register.

**Alternative Configurations** Multiple A3942s can be configured together.

- **Standalone Connection** In this configuration, the master simultaneously shifts eight bits in through the SDI pin and shifts eight bits out of the SDO pin. First, the CSZ pin is set low. Then, the Output Fault register is loaded with the relevant fault byte (see the Output Fault Register topic below). Eight clock cycles are used to perform the shifts.
- **Parallel Connection** Because each slave has a CSZ pin, operation is identical to the Standalone configuration. When CSZ is inactive, SDI is “don’t care” and SDO is high impedance.
- **Daisy Chain Connection** The master shifts  $n$  bytes (eight bits each) during  $n \times 8$  clock cycles. Regardless of the position of an individual A3942 slave in the daisy chain, the slaves shift the output byte during the first eight clock cycles after CSZ goes low. When CSZ goes high, the eight bits in the Shift register are latched into the Input register.

**Serial Port Disabling** Disable the serial port by setting the CSZ pin high while in sleep mode. This loads the Input register with default values, all zeroes (0).

**Serial Port Error Handling** Input data is discarded if the number of bits in an input stream are not a multiple of eight. Furthermore, unless the number of clock cycles is a multiple of eight while CSZ is active, any bits shifted in from the SDI pin are discarded.

**Input Register Operation** After a valid byte is latched into the Input register from the shift register, bit D5 is evaluated to determine if the byte is to be read. An inactive (0) bit value causes all other bits to be ignored.

If bit D5 is active (1) the other bits are read and decoded. Bits D6 and D7 are used to determine which output channel is updated. Bits D0 through D4 set the channel-specific operation, including clearing and masking of faults.

**Output Fault Register Operation** This register is loaded with fault data to be shifted out through the SDO pin. No handshaking is required.

The Output Fault register contains data on active faults. Four internal channel-specific fault registers contain any latched fault data for each respective channel. The following describes how the A3942 determines which channel-specific fault register to transfer into the Output Fault register.

- **No Faults** If there are no current faults, the Output Fault register is loaded with all zeros:

```
00 000 000
```

- **Single Fault** If there is only one fault detected, the Output Fault register is filled to indicate that fault.

For a load fault, the Address bits are set to indicate the affected channel; for example, a short-to-battery on channel 3 would be written:

```
10 000 010
```

On the other hand, for system faults, the Address bits are irrelevant, and a CP UVLO fault would be loaded as:

```
00 010 000
```

with the Address bits defaulting to 00.

- **Multiple System Faults** If there are multiple system faults, the Output Fault register is loaded with the setting for each system fault (the Address bits remain irrelevant, as in the case of a single fault). For example, when CP UVLO and Thermal Warning faults both have occurred, the Output Fault register is loaded with:

```
00 011 000
```

- **Multiple System Faults and Single Channel Load Fault** If one or more system faults and one or more load faults from a single channel have occurred, all faults are loaded into the Output Fault register, with the channel of the load faults indicated in the Address bits. For example, a CP UVLO system fault and an STG load fault on Channel 2 would be written as:

```
01 010 001
```

- **Multiple Channel Load Faults** When load faults occur on more than one channel, the data cannot be signalled in a single SDO byte. However, the data can still be retrieved. The A3942 polls each channel-specific fault register, in ascending order by channel number.

Each output is delimited by the appropriate CSZ event. For example, assume an OL on channel 2 and an STG on Channel 4. The first CSZ event writes:

```
01 000 100
```

and the second CSZ writes:

```
11 000 001
```

In summary, all faults are retrieved by issuing consecutive CSZ events until the channel number stops increasing.

- If there are no faults, this byte will be shifted out each time:

```
00 000 000
```

- If there are only system faults, this byte will be shifted out each time:

```
00 [1|0] [1|0] [1|0] 000
```

- If there are system faults and only one load fault, one byte contains all of the fault data.

- If there are load faults on more than one channel, these bytes would be shifted out in succession, and any existing system faults will be indicated. For example, if there were no system faults and load faults on channels 2, 3, and 4, the following series of bytes would be shifted out:

```
01 000 [1|0] [1|0] [1|0]
```

```
10 000 [1|0] [1|0] [1|0]
```

```
11 000 [1|0] [1|0] [1|0]
```

```
01 000 [1|0] [1|0] [1|0]
```

```
. . .
```

## APPLICATIONS

**Unused Outputs** When any of the four output channels are not used, the related pins should be connected as follows:

| Unused Channel Pin | Connection |
|--------------------|------------|
| INx                | GND        |
| Sx                 | GND        |
| Dx                 | VBB        |
| Gx                 | Floating   |

**RREF Selection** The tolerance on RREF can be as high as  $\pm 4\%$ . Depending on how a specific part changes over temperature changes and lifetime, the  $\pm 4\%$  range generally covers nominal 1% resistors.

The parameters which are affected by changes in RREF are listed in the following table:

| Parameter                   | Change as RREF Tolerance |           |
|-----------------------------|--------------------------|-----------|
|                             | Increases                | Decreases |
| $I_{REF}$                   | —                        | +         |
| $t_{RESET}$                 | +                        | —         |
| $t_{SLEEP}$                 | +                        | —         |
| $t_{WAKE}$                  | +                        | —         |
| $I_{G(HI)}$ and $I_{G(LO)}$ | —                        | +         |
| $I_{OL}$                    | —                        | +         |
| $t_{ON}$ and $t_{OFF}$      | +                        | —         |

**Setting Fault Circuit Trip Levels** The load faults, Short-to-Battery (STB), Short-to-Ground (STG), and Open Load (OL), are all latched. The thresholds for STG and OL faults can be set by the value for the RDx resistor.

**Open Load Fault Level** When the gate output is switched off, by setting it off with the input pin or through SPI, or due to a latched fault, a current,  $I_{OL}$ , is sourced to Sx to detect if the load is still in the circuit.  $V_{OL}$  is compared to

$$I_{OL} \times [R_L // R_{GS}]$$

to evaluate an OL fault.

If the load has been removed,  $V_{Sx}$  exceeds  $V_{OL}$  and a fault is registered.  $V_{Sx}$  would drift to  $V_{BB}$  when an open load exists and thereby inadvertently trip a nuisance STB fault. To prevent this, the Sx pin is clamped to  $V_{CLAMP}$ .

The operating limits specified in the Electrical Characteristics table allow the fault circuitry to distinguish all faults within the operating range of  $V_{BB}$ . If, however, the specified limits on  $V_{Dx}$  are too restrictive at low  $V_{BB}$  levels, the only repercussion is a nuisance STB fault, and this only occurs when an OL condition exists. The limit on  $V_{Dx}$  can be ignored either if the off-state faults are masked or if it is acceptable to latch the nuisance fault and clear it when the OL fault is cleared.

Because  $V_{OS} \ll V_{OL}$ , a fault is registered if

$$I_{OL} \times R_L // R_{GS} > V_{OL}.$$

Hence, the trip level,  $R_L(\text{trip})$  is:

$$R_L(\text{trip}) = \left( \frac{I_{OL}}{V_{OL}} - \frac{1}{R_{GS}} \right)^{-1}$$

The OL circuit and its tolerances are designed to ensure that external resistive loads above 50 k $\Omega$  are identified as open load and that resistive loads below 10 k $\Omega$  are identified as valid. Note that these numbers are only valid for resistive loads. If the output load has a capacitive element, then the blank time must be long enough to allow the capacitors to charge or discharge to the steady-state voltage level. As a result, blanking times must be set appropriately for a given load.

Under normal conditions, when the external MOSFET is off, and the load is in circuit,

$$I_{OL} \times R_L < V_{OL}.$$

When a load becomes disconnected, the open load condition will normally not be detected until the gate drive output is switched off. However, if the load has an inductance, either as an inductive

coil load or due to load wiring, and it becomes open circuit while it is carrying current, there may be a large transient voltage at the load connection. This in turn can cause transient voltage on VSx and VDx, creating a false STG fault. If an STG fault is detected, then the gate drive output will be switched off and the both STG and OL faults, and possibly an STB fault, will be reported.

**Short-to-Battery Fault Level** The STB comparator compares the load voltage

$$I_{OL} \times R_L // R_{GS}]$$

to the voltage set by RDx,

$$V_{BB} - I_D \times R_D.$$

The comparator is active only when the gate drive output is switched off, by setting it off with the input pin or through SPI, or due to a latched fault.

During an STB condition,  $I_{OL} = 0$  because the current source has run out of headroom. A fault is registered when

$$V_L > V_{BB} - I_D \times R_D \pm V_{OS}.$$

That is, the load voltage is within  $\Delta V = I_D \times R_D$  volts of  $V_{BB}$ .

Using  $V_{DS} = V_{BB} - V_L$  and rearranging, we find that

$$V_{DS} < I_D \times R_D \pm V_{OS}.$$

Therefore,

$$R_D = (V_{DS}(\text{trip}) \pm V_{OS}) / I_D,$$

which is also the case for STG faults, described below. Note that an STB condition generally latches the OL flag as well.

Under normal conditions  $R_L \ll R_{GS}$  and  $I_{OL}$  flows through the load, given

$$I_{OL} \times (R_D + R_L) < V_{BB} - I_D \times R_D \pm V_{OS}.$$

Because  $I_{OL} \times (R_D + R_L) \approx 0$  when the external MOSFET is off, no fault is registered.

**Short-to-Ground Fault Level** The effect of the STG comparator is to compare the external MOSFET  $V_{DS}$  ( $V_L$ ) to the set trip voltage  $V_{BB} - I_D \times R_D$ .

The comparator is active only when the gate is commanded on. Also, the sourced current  $I_{OL}$  is deactivated.

If  $V_{DS}$  is too large, an STG fault is registered when

$$V_L < V_{BB} - I_D \times R_D \pm V_{OS},$$

or, because the external MOSFET  $V_{DS} = V_{BB} - V_L$ ,

$$V_{DS} > I_D \times R_D \pm V_{OS}.$$

Therefore, the STG trip level in the on state is the same as the STB level in the off state:

$$R_D = (V_{DS}(\text{trip}) \pm V_{OS}) / I_D.$$

Converse to the preceding, in normal operation

$$V_L > V_{BB} - I_D \times R_D \pm V_{OS},$$

or

$$V_{DS} < I_D \times R_D \pm V_{OS}.$$

## Power Limits

Power dissipation,  $P_D$ , is limited by thermal constraints. The maximum junction temperature,  $T_J(\text{max})$ , and the thermal resistance,  $R_{\theta JA}$ , are given in this datasheet. The maximum allowed power is then found for a given ambient,  $T_A$ , from this equation:

$$T_J = P_D \times R_{\theta JA} + T_A, \text{ or} \\ P_D = (T_J - T_A) / R_{\theta JA}.$$

The three main contributions to power dissipation are:

- quiescent supply,  $P_{BB(Q)}$
- driver outputs,  $P_{DRV}$ , and
- logic level supply,  $P_{DD}$ .

These three terms appear in the following equation:

$$P_D = P_{BB(Q)} + P_{DRV} + P_{DD}.$$

The quiescent supply current leads to a baseline power loss:

$$P_{BB(Q)} = V_{BB} \times I_{BB(Q)}.$$

In general, the losses in a driver can be quantified as follows. Given that the driver current leaves  $G_x$  to charge a gate, and assuming that the external circuit is approximately lossless, then the same charge is sunk back into  $G_x$ . Therefore, all driver current can be treated as going to heat the chip.

Total current into  $V_{BB}$  includes the quiescent current,  $I_{BB(Q)}$ , plus additional current,  $\Delta I_{BB}$ , to energize the gates. The latter is three times the average gate current:

$$\Delta I_{BB} = 3 \times I_{Gx(av)}.$$

The average load current is calculated using the gate charge,  $Q_G$ , from the external MOSFET datasheet and the switching frequency:

$$I_{Gx(av)} = f_{sw} \times Q_G.$$

If all four outputs are supplying this current,

$$\Delta I_{BB} = 4 (3 \times I_{Gx}) = 12 \times f_{sw} \times Q_G,$$

and

$$P_{DRV} = V_{BB} \times \Delta I_{BB} = 12 \times f_{sw} \times Q_G \times V_{BB}.$$

Finally, loss in the logic circuits is

$$P_{DD} = V_{DD} \times I_{DD}.$$

*Example:*

Find the junction temperature with one IRFZ44ES MOSFET at each output, being switched at 5 kHz, and given  $V_{BB} = 14$  V and  $V_{DD} = 5.5$  V.

Answer: The IRFZ44ES datasheet gives  $Q_G(\text{max}) = 60$  nC (note that this parameter depends on circuit design constraints, such as  $V_{DS}$ ). The Electrical Characteristics table gives the following maximum values for the A3942:  $I_{BB(Q)} = 10$  mA,  $V_{DD} = 5.5$  V, and  $I_{DD} = 3$  mA.

First, calculate total power loss:

$$P_D = V_{BB} I_{BB(Q)} + 12 f_{sw} Q_G V_{BB} + V_{DD} I_{DD} \\ = 14 \text{ V} \times 11 \text{ mA} \\ + 4 \times 3 \times 5 \text{ kHz} \times 60 \text{ nC} \times 14 \text{ V} \\ + 5.5 \text{ V} \times 3 \text{ mA} \\ = 221 \text{ mW}.$$

Then, the junction temperature can be found for a given ambient temperature;  $T_A = 125^\circ\text{C}$  is assumed here. Thermal resistance depends significantly on the board design;  $R_{\theta JA} = 100^\circ\text{C/W}$  is assumed here. Substituting these values:

$$T_J = P_D \times R_{\theta JA} + T_A \\ = 221 \text{ mW} \times 100^\circ\text{C/W} + 125^\circ\text{C} \\ = 147^\circ\text{C}.$$

## LAYOUT AND COMPONENTS

General good practices should be followed. In addition, the following are recommended:

- Locate bypass capacitors ( $V_{BB}$ ,  $V_{DD}$ ,  $V_{REG}$ , and  $I_{REF}$ ) as close to the A3942 as practicable.
- Traces to bypass capacitors should be as wide as practicable; minimize the number of vias.
- Use both bulk storage capacitors (for example, electrolytic) and low impedance bypass capacitors (for example, ceramic) on all supply pins. See the Functional Block Diagram for recommended values.
- Input and output lines should not be in close proximity. If they

do overlap, it should be at right angles.

- Use ample copper in the ground and power paths. Use planes or fills where possible.
- The A3942 ground and VBB supply should be star-connected to the power ground and supply.
- The trace connecting the RDx resistors to the A3942 Dx pins should be as short as possible.
- The trace leaving the other side of the RDx resistors can be long because it has a low impedance path to ground; however, it must run independently to the respective external MOSFET in order to make a Kelvin connection.
- All support capacitors are to be referenced to the A3942 ground plane or ground fill. Minimize loop area of traces.
- These traces should be as wide as practicable: VBB, VDD, VREG, VCP, and Gx. Secondly, it is also preferred that the traces to the charge pump caps be as wide as practicable. In both cases, the number of vias should be minimized.
- Minimize the distance connecting to ground pins in order to minimize ground loops.

Finally, a note about thermals. Because the A3942 ground pins are internally fused to the die mounting pad, they are the main path for heat dissipation. In applications producing high junction temperatures, care must be given to designing the thermal path. For example, multiple thermal vias should be run from ground pins down to the ground plane. If space allows, wide traces from ground pins to exposed copper fills on the top layer efficiently release heat through convection cooling.

## Terminal List

| No. | Name   | Pin Description                |
|-----|--------|--------------------------------|
| 1   | SDO    | Serial Data Out                |
| 2   | SDI    | Serial Data In                 |
| 3   | SCLK   | Serial Clock                   |
| 4   | CSZ    | Chip Select – NOT              |
| 5   | FAULTZ | Fault – NOT (Open Drain)       |
| 6   | RESETZ | Reset – NOT (Discrete)         |
| 7   | ENB    | Enable (Discrete)              |
| 8   | VDD    | Logic Supply                   |
| 9   | IREF   | Current Reference Pin          |
| 10  | GND    |                                |
| 11  | IN2    | Discrete Input Channel 2       |
| 12  | IN1    | Discrete Input Channel 1       |
| 13  | D2     | Channel 2: Drain               |
| 14  | D1     | Channel 1: Drain               |
| 15  | GND    |                                |
| 16  | S1     | Channel 1: Source              |
| 17  | G1     | Channel 1: Gate                |
| 18  | G2     | Channel 2: Gate                |
| 19  | S2     | Channel 2: Source              |
| 20  | S3     | Channel 3: Source              |
| 21  | G3     | Channel 3: Gate                |
| 22  | G4     | Channel 4: Gate                |
| 23  | S4     | Channel 4: Source              |
| 24  | GND    |                                |
| 25  | D3     | Channel 3: Drain               |
| 26  | D4     | Channel 4: Drain               |
| 27  | IN3    | Discrete Input Channel 3       |
| 28  | IN4    | Discrete Input Channel 4       |
| 29  | VREG   | Internal Regulator             |
| 30  | VBB    | Power Supply                   |
| 31  | GND    |                                |
| 32  | VCP    | Reservoir Capacitor Terminal   |
| 33  | CP1    | Charge Pump Capacitor Terminal |
| 34  | CP3    | Charge Pump Capacitor Terminal |
| 35  | CP2    | Charge Pump Capacitor Terminal |
| 36  | CP4    | Charge Pump Capacitor Terminal |
| 37  | GND    |                                |
| 38  | GND    |                                |

LG Package, 38-Pin TSSOP
