# **GENERAL DESCRIPTION**

The ADP1074 is a current mode, fixed frequency, active clamp, synchronous forward controller designed for isolated dc to dc power supplies. Analog Devices proprietary *i*Couplers\* are integrated in the ADP1074 to eliminate the bulky signal transformers and optocouplers that transmit signals over the isolation boundary. Integrating the *i*Couplers reduces system design complexity, cost, and component count and improves overall system reliability. With the integrated isolators and metal-oxide semiconductor field effect transistor (MOSFET) drivers on both the primary and the secondary side, the ADP1074 offers a compact system level design and yields a higher efficiency than a non-synchronous forward converter at heavy loads.

The primary side pins provide functions for programming the switching frequency, maximum duty cycle, external frequency synchronization, and slope compensation.

The secondary side pins provide functions for differential output voltage sensing, overvoltage, power good, tracking, and programmable light load mode setting.

The feedback signal and timing of synchronous rectifier pulse-width modulations (PWMs) are transmitted from primary to secondary or from secondary to primary sides through the *i*Couplers using a proprietary transmission scheme.

The ADP1074 also offers features such as input current protection, undervoltage lockout (UVLO), precision enable with adjustable hysteresis, overtemperature protection (OTP), and power saving light load mode (LLM).

<sup>&</sup>lt;sup>1</sup> Versions of these devices are available with controlled manufacturing to support the quality and reliability requirements of automotive applications. These models are designated with a W suffix. Only the automotive grade products shown are available for use in automotive applications. Contact a local Analog Devices account representative for specific product ordering information and to obtain the specific automotive reliability reports for these models.

<sup>&</sup>lt;sup>2</sup> Some packages are available in 500 unit reels through designated sales channels. These versions feature the #TRMPBF suffix.

<sup>3</sup> Contact the factory for devices specified with wider operating temperature ranges. The temperature grade is identified by a label on the shipping container.

# **SPECIFICATIONS**

VIN = 24 V, VDD2 = 12 V,  $T_J$  = -40°C to +125°C, unless otherwise noted.

<sup>&</sup>lt;sup>1</sup> Refers to common-mode transients across the insulation barrier. Common-mode transients exceeding the absolute maximum rating can cause latch-up or permanent damage.

Stresses at or above those listed under Absolute Maximum Ratings may cause permanent damage to the product. This is a stress rating only; functional operation of the product at these or any other conditions above those indicated in the operational section of this specification is not implied. Operation beyond the maximum operating conditions for extended periods may affect product reliability.

# THERMAL RESISTANCE

Thermal performance is directly linked to printed circuit board (PCB) design and operating environment. Careful attention to PCB thermal design is required.

Table 9. Thermal Resistance<sup>1</sup>

# **ESD CAUTION**

**ESD** (electrostatic discharge) sensitive device. Charged devices and circuit boards can discharge without detection. Although this product features patented or proprietary protection circuitry, damage may occur on devices subjected to high energy ESD. Therefore, proper ESD precautions should be taken to avoid performance degradation or loss of functionality.

# PIN CONFIGURATIONS AND FUNCTION DESCRIPTIONS

Figure 4. 24-Lead SOIC\_W Pin Configuration

Figure 5. 24-Terminal LGA Pin Configuration

# **Table 12. Pin Function Descriptions**

| Pin No. | Mnemonic | Description   |  |
|---------|----------|---|--|
| 1       | NGATE    | Driver Output for the Main Power MOSFET on the Primary Side. Multiple function pin. Connect a resistor from NGATE to PGND1 to set up the predetermined dead time between PGATE and SR2.   |  |
| 2       | PGATE    | Driver for the Active Clamp MOSFET of the Forward Topology. This pin is referenced to PGND1.  |  |
| 3       | PGND1    | Power Ground on the Primary Side. Star connect this pin to AGND1.   |  |
| 4       | AGND1    | Analog Ground on the Primary Side. Star connect this pin to PGND1. Use this pin to differentially sense the primary current sensed with the sense resistor between the CS and AGND1 pins.   |  |
| 5       | VREG1    | 8 V Output for the MOSFET Drivers. Connect 1 $\mu$ F or greater at this pin. Do not put an external load on this pin. Reference this pin to PGND1.  |  |
| 6       | VIN      | Input Voltage. Connect a 4.7 µF capacitor to this pin. The size of this capacitor can be reduced if the input voltage to this pin is guaranteed stable. Reference this pin to PGND1.  |  |
| 7       | EN       | Precision Enable Input. The controller is enabled when the voltage at the EN pin is above the EN threshold voltage. Soft stop is enabled when EN drops below the EN threshold voltage. This pin also has a programmable EN hysteresis. Reference this pin to AGND1.   |  |
| 8       | CS       | Input Current Sensing. This pin senses the input pulse width modulated current. Place a current sense resistor between the source terminal of the power MOSFET and PGND1. This current sense resistor sets up the input current limit. This pin is also used for an external slope compensator. Connect a resistor from CS to the current sense resistor to generate a voltage ramp for the slope compensation. Reference this pin to AGND1. Connect a 33 pF to 100 pF capacitor to this pin to act as a resistor capacitor (RC) filter along with the slope compensation resistor in noisy environments. |  |
| 9       | RT       | Switching Period Resistor. Connect two resistors in series that sum up to the appropriate resistor from RT to AGND1 to set the switching frequency. See the DMAX pin for more information. Also see the Frequency Setting (RT Pin) section and the Maximum Duty Cycle section for the relevant equations.   |  |
| 10      | SYNC     | Frequency Synchronization. Connect an external clock to the SYNC pin to synchronize the internal oscillator to this external clock frequency. Connect SYNC to AGND1 if this feature is not used. It is recommended that the SYNC frequency be within 10% of the frequency set by the RT pin.  |  |
| 11      | SS1      | Soft Start 1. Connect a capacitor at this pin to set up the open-loop soft start time. Reference this pin to AGND1.   |  |
| 12      | DMAX     | Maximum Duty Cycle Control. Connect DMAX to the center tap of the resistive divider at the RT pin to set up the maximum duty cycle. See the Frequency Setting (RT Pin) section and the Maximum Duty Cycle section for the relevant equations.   |  |
| 13      | MODE     | Light Load Mode Setting. Connect MODE to AGND2 to disable discontinuous conduction mode (DCM) operation, or to a high logic (2.5 V or higher, such as the VREG2 pin) to force LLM operation, or to a resistor to sup a fixed LLM threshold voltage.   |  |
| 14      | PGOOD    | Power Good Pin. Open-drain output. Connect a pull-up resistor from PGOOD to VREG2.  |  |
| 15      | SS2      | Soft Start on the Secondary Side. Connect a capacitor from SS2 to AGND2 to set up the soft start time on the secondary side.  |  |

| Pin No. | Mnemonic | Description  |
|---------|----------|--|
| 16      | COMP     | Compensation Node on the Secondary Side. This pin is the output of the transconductance (gm) amplifier. This pin is referenced to AGND2.   |
| 17      | FB       | Feedback Node on the Secondary Side. Set up the resistive divider from the output voltage such that the nominal voltage, when the power supply is in regulation, is 1.2 V. Reference this pin to AGND2.  |
| 18      | OVP      | Output Overvoltage Protection (OVP). The OVP threshold is set at 1.36 V. Connect a resistive divider from OVP to the output and AGND2.   |
| 19      | VDD2     | Input Supply on the Secondary Side. Connect VDD2 to the output voltage of the power supply for a self driven configuration. Connect a 4.7 $\mu$ F capacitor from VDD2 to AGND2. The size of this capacitor can be reduced if the input voltage to VDD2 is guaranteed stable. |
| 20      | VREG2    | 5 V Regulated Low Dropout (LDO) Output for Internal Bias and Powering of the Drivers of the Synchronous Rectifiers. Do not use VREG2 as a reference or load. Connect a 1 µF capacitor from VREG2 to AGND2.   |
| 21      | AGND2    | Analog Ground on the Secondary Side. Star connect AGND2 to PGND2. Use AGND2 for differential sensing of the output voltage between the FB pin and AGND2.   |
| 22      | PGND2    | Power Ground on the Secondary Side. Star connect PGND2 to AGND2.   |
| 23      | SR2      | MOSFET Driver Output 2 for the Synchronous Rectifier MOSFET. This PWM controls the freewheeling switch.  |
| 24      | SR1      | MOSFET Driver Output 1 for the Synchronous Rectifier MOSFET. This PWM is in phase with NGATE.  |

# THEORY OF OPERATION

The ADP1074 is a current mode, fixed frequency, active clamp, synchronous forward controller designed for isolated dc to dc power supplies. Analog Devices proprietary *i*Couplers are integrated in the ADP1074 to eliminate the bulky signal transformers and optocouplers that transmit signals over the isolation boundary. Integrating the *i*Couplers reduces system design complexity, cost, and component count and improves overall system reliability. With the integrated isolators and MOSFET drivers on both the primary and the secondary side, the ADP1074 offers a compact system level design and yields a higher efficiency than a nonsynchronous forward converter at heavy loads.

Traditionally in a forward or flyback converter, a discrete optocoupler is used in the feedback path to transmit the signal from the secondary to the primary side, and an external transformer is used for transmitting the PWM signal from the primary to the secondary side for synchronous rectification. However, the current transfer ratio (CTR) of the optocouplers degrades over time and over temperature and so the optocoupler must be replaced every five to ten years, depending on the manufacturing quality and optocoupler grade that determines the initial CTR. The ADP1074 eliminates the use of optocouplers and signal transformers, thus reducing system cost, PCB area, and complexity while improving system reliability, without the issue of CTR degradation of the optocouplers.

The ADP1074 controller offers a complete solution for an isolated dc to dc power supply by integrating the 5 kV isolators and the primary and secondary control circuitries in one package.

The PWM controls are performed on the primary side by sensing the input peak current cycle by cycle with a sense resistor at the source of the main switching MOSFET. The output of the converter is sensed by the secondary circuitry, which sends the feedback and PWM signals to the primary side via the 5 kV integrated isolators for a complete control loop solution.

The primary circuitry in the ADP1074 includes an 8 V LDO, input current sensing, bias circuit, and MOSFET drivers including an active clamp reset driver, slope compensation, external frequency synchronization, PWM generator, and a programmable maximum duty cycle setting. The primary side also has pins for differential sensing of the current sense signal.

The secondary circuitry includes the feedback compensation, a 5 V LDO regulator, an internal reference, two MOSFET drivers for synchronous rectification, and a dedicated pin for overvoltage protection. Additionally, the secondary side features differential output voltage sensing and power good pins, and a programmable light load mode setting.

The integrated *i*Couplers carry out the communications between the primary and secondary sides by transmitting the feedback signal and the PWMs over the isolation barrier.

The feedback signal and timing of synchronous rectifier PWMs are transmitted between the primary and the secondary sides, or between the secondary and primary sides, through the *i*Couplers using a proprietary transmission scheme.

The ADP1074 also offers features such as input current protection, UVLO, precision enable with adjustable hysteresis, OTP, LLM, and tracking.

# **DETAILED BLOCK DIAGRAM**

Figure 13 shows a detailed block diagram of the ADP1074.

Figure 13. Detailed Block Diagram

# PRIMARY SIDE SUPPLY, INPUT VOLTAGE, AND LDO

Two pins on the primary side are supply pins: VIN and VREG1. A high voltage LDO regulator connected to VIN has a regulated output of 8 V at the VREG1 pin. This LDO regulator provides power to the internal bias circuitry, primary side *i*Couplers and housekeeping circuits, and the primary MOSFET drivers at the NGATE and PGATE pins.

To reduce power consumption in the LDO for input voltages higher than approximately 30 V, an auxiliary winding on the transformer of the active clamp forward topology can be used to power VREG1. This auxiliary supply voltage must be higher than the regulated output at VREG1 so that the LDO shuts off during normal operation. The recommended auxiliary voltage is  $\geq$ 8.5 V and  $\leq$ 13 V because an internal 14 V Zener diode is connected at VREG1.

For a high input voltage application to avoid losses in the LDO, connect the VIN and VREG1 pins together and apply an auxiliary voltage of 8 V to 10 V, which exceeds the VIN pin UVLO of typically 4.5 V. Take care that this voltage does not exceed the internal Zener clamp voltage of 14 V (typical). The typical value is 10 V.

# **SECONDARY SIDE SUPPLY AND LDO**

Two pins on the secondary side are supply pins: VDD2 and VREG2.

The secondary side is typically powered by the output rail of the converter by connecting it to the VDD2 pin. The UVLO for the secondary side is typically 3.5 V, at which the secondary side starts up. For output voltages less than the secondary UVLO voltage, a third winding is required to generate an auxiliary voltage to power the secondary circuitry. The internal 5 V LDO regulator at the VREG2 pin powers the MOSFET drivers, secondary side *i*Couplers, and housekeeping circuits. When VDD2 is less than 5 V, the LDO regulator operates in dropout mode.

For output voltages higher than 24 V, connecting the output voltage directly to VDD2 can result in significant power dissipation in the LDO. For instance, at 24 V and with the total driver current at 10 mA, the power dissipated in the LDO is 0.19 W (10 mA  $\times$  19 V). It is recommended to power VDD2 with an auxiliary voltage in the 8 V to 12 V range.

#### PRECISION ENABLE

The enable threshold at the EN pin is precision voltage referenced at 1.2 V. Assuming VIN is above the UVLO voltage (typically 4.5 V), the ADP1074 is enabled when the voltage at EN rises above 1.2 V. The crossing of the voltage, such that  $V_{\text{EN}} > 1.2 \text{ V}$ , enables the internal 8 V LDO regulator on the VREG1 pin, and, after the internal biasing is finished, a soft start procedure is initiated.

Connect a resistive divider between EN and VIN to set up the input start-up voltage (see Figure 14.) An internal current source at EN allows the user to program the UVLO start-up voltage with a desirable hysteresis. To calculate the start-up voltage with

hysteresis, use the superposition theorem or nodal analysis to obtain the EN pin voltage, as follows:

$$V_{EN} = V_{IN} \times \frac{R2}{R1 + R2} - I_{EN} \times (R1 || R2 + RH)$$

where:

 $V_{EN}$  is the EN pin voltage.

 $I_{EN}$  is the current source at the EN pin (1  $\mu$ A for turn on and 4  $\mu$ A for turn off).

The user can adjust the R1, R2, and RH resistors such that  $V_{\text{EN}} \ge 1.2 \text{ V}$  and obtain the desired hysteresis.

An internal 1  $\mu A$  pull-down current is always on, and the 3  $\mu A$  current is active only when the  $V_{EN}$  is below the EN threshold and becomes inactive when  $V_{EN}$  is above the EN threshold.

In general, a higher input voltage requires a larger hysteresis. It is recommended to keep a capacitor on the EN pin to AGND1 to provide a low impedance path that prevents any noise, which toggles the EN pin when the input voltage hovers at the threshold.

Figure 14. Precision EN with Adjustable Hysteresis

When the EN pin is less than the EN threshold, the system enables the soft stop procedure. SR1 and SR2 take up to a maximum of two switching periods to terminate. See the Soft Start Procedure section for more details.

# **SOFT START PROCEDURE**

The following procedure assumes that the VDD2 pin is powered directly from the output voltage of the power supply.

To ensure a smooth output voltage ramp during startup, the soft start sequence is controlled by two soft start control circuits, one in the primary (for open-loop soft start, using the SS1 pin) and the other in the secondary (for closed-loop soft start, using the SS2 pin). Proper handshaking between the primary side and the secondary side is needed prior to the secondary side taking control.

The open-loop soft start time is determined by the capacitor on the SS1 pin. This pin sources a 9.1  $\mu A$  constant current that builds up a voltage on the SS1 pin. The voltage on the SS1 pin is proportional to the peak primary current limit where 0 V and 1.5 V correspond to a peak current of 0 A and 120 mV/R\_SENSE, respectively. This rate is the open-loop soft start. During this time, the ADP1074 starts firing the PWM pulses, and the output voltage continues to build up slowly if the average inductor current limit exceeds the load current. Because the ADP1074 is a current mode controller, the output capacitor

starts charging only when the primary current limit exceeds the load current requirement.

The rate at which the SS1 pin voltage rises to the maximum current limit is given by

$$dt = C_{SS1} \times 1.5/(9.1 \,\mu\text{A})$$

The handshaking process is as follows.

When VDD2 reaches the UVLO of approximately 3.5 V, the internal circuitry on the secondary side is activated and the ADP1074 initiates the following process:

- 1. The ADP1074 makes the voltage on the SS2 pin equal to the value on the FB pin, with an SS2 pin current, at ten times the nominal current source of 20  $\mu$ A on the SS2 pin.
- Simultaneously, the current limit on the primary (which is the voltage on SS1) is transferred over to the secondary side, and the voltage on the COMP pin is made equal to the instantaneous SS1 voltage ± 100 mV. There is a timeout for this process, which is 1.5 ms after the VDD2 UVLO threshold is crossed.

When this process is satisfied, the transmission of the COMP signal occurs from the secondary to the primary side. The ADP1074 transmits the COMP signal by continuously sampling the analog signal at the COMP pin. The sampled value is then transmitted using a proprietary scheme to the primary side where the instantaneous value of the CS pin is compared to the COMP level to determine the falling edge of the NGATE pulse. The COMP signal is, therefore, a representation of the primary current limit.

After COMP transmission begins, the primary side receives the signal and control is completely handed over to the secondary side when either the received level of COMP on the primary side is within  $\pm 100$  mV, or up to 128 switching periods (typically 8) have passed, starting from the first pulse being transmitted to the primary side.

Then, the control is handed over to the secondary side and the closed-loop soft start begins, where the SS2 capacitor is charged at a nominal rate of 20  $\mu A$ . The output voltage then rises to the regulation voltage based on the SS2 pin voltage. The voltage on the SS2 pin continues to rise to 1.2 V, that is, the steady state voltage on the FB pin. At this stage, the power supply is in regulation, and the output voltage is at its target value.

At the end of the soft start process, the voltage on the SS2 pin continues to rise to approximately 1.4 V. The instant that the handover takes place, SS1 is discharged to 0 V. In steady state, the FB pin (that is, the reference voltage) is 1.2 V.

The SR1 and SR2 synchronous drivers begin to pulse after VDD2 crosses the UVLO threshold.

If the voltage at the VDD2 pin is greater than the UVLO voltage, such as a soft start from the precharged output, or if the VDD2 pin is powered by an external supply, the secondary side assumes control from the moment the EN pin is enabled, and only SS2 is used for the soft start procedure.

When initiating a soft start from the precharged output, the SS2 pin tracks the FB pin and then initiates a soft start. This process eliminates any glitches in the output voltage.

When soft starting into a precharged output, the SRx gates are prevented from turning on until the SS2 voltage has reached the precharged voltage at the FB pin. This soft start scheme prevents the output from being discharged, and it prevents reverse current.

Under abnormal situations, such as a shorted load or a transient condition on the load during the soft start process, FB may not be able to track SS2 accurately. If this occurs before the VDD2 UVLO threshold is crossed, SS1 is in control. If it occurs after the VDD2 UVLO threshold is crossed, SS2 tracks the FB pin and then continues with the soft start process until the regulation voltage is reached. In all conditions, control is handed over to the secondary if FB  $\geq$  1.2 V.

When the secondary VDD2 is directly powered by the output of the converter, the minimum output voltage required is higher than the secondary UVLO voltage. For output voltages less than the secondary UVLO voltage, a third winding is needed to generate an auxiliary voltage to power the secondary side circuitry. Alternately, in most cases, a diode resistor capacitor combination from the switch node can provide the voltage to VDD2.

# **OUTPUT VOLTAGE SENSING AND FEEDBACK**

The output voltage of the converter is set by a resistive divider to the FB pin. The resistive divider must be set in a manner such that the voltage at the FB pin is 1.2 V in steady state. The output voltage must be differentially sensed using the FB pin and the AGND2 pin.

# LOOP COMPENSATION AND STEADY STATE OPERATION

The FB pin feeds into the negative terminal of a transconductance amplifier (or gm amplifier) with a gain of approximately 250  $\mu A/V$ . The positive input terminal of the gm amplifier is connected to SS2, which provides the reference setpoint voltage. The output of the gm amplifier is connected to the COMP pin. The voltage on the COMP pin is representative of the current peak limit required to sustain regulation. This pin is continuously sampled, and the signal is transmitted to the primary side, where it is compared to the sensed primary current using a comparator. When the comparator trips, it causes NGATE to terminate.

Typically, an RC network in series is connected between the COMP pin and AGND2 for compensation. A high frequency pole in the form of a capacitor can also be added in parallel to the RC network.

The output of the gm amplifier is clamped to a minimum and maximum current of approximately –57  $\mu A$  and +43  $\mu A,$  respectively.

The COMP node is clamped to a lower and higher level of approximately 0.7 V and 2.52 V, respectively. This is representative of the CS range from 0 mV to 120 mV.

#### **SLOPE COMPENSATION**

For a peak current mode controller with duty cycle higher than 50%, slope compensation is necessary for a stable operation. To set up an external compensation in the ADP1074, connect the external  $R_{\text{RAMP}}$  resistor (see Figure 25) between CS and the current sense resistor,  $R_{\text{SENSE}}$ , to set up the slope voltage ramp for the control signal. It is important to sense the signal differentially. See the Layout Guidelines section for more details.

An internal ramp current starts from 0  $\mu$ A at the minimum duty cycle (that is, the beginning of the switching period) and increases linearly toward a maximum of 20  $\mu$ A at the end of the switching period. The slope of the voltage ramp is the ramp current times  $R_{RAMP}$ .  $R_{RAMP}$  is sized using the following equation:

$$R_{RAMP} \ge k \frac{V_{OUT}}{L} \times \frac{N2}{N1} \times \frac{R_{SENSE}}{20 \ \mu A} \times t_{S}$$

where:

k=0.5 for nominal cases and k=1 for deadbeat control.

 $V_{OUT}$  is the desired output voltage.

*L* is the output inductor.

N1 and N2 are the primary and secondary turns of the transformer.

 $t_{S}$  is the switching period.

# INPUT/OUTPUT CURRENT-LIMIT PROTECTION

There is no direct current-limit sensing circuit on the secondary; the output current limit is indirectly limited by the cycle-by-cycle primary side current limit of 120 mV on the CS pin.

The input peak current limit is set by connecting a sense resistor,  $R_{\text{SENSE}}$ , from the source of the main MOSFET to PGND1 (see Figure 25), and the sensed voltage appears at the CS pin. To generate the slope-comp ramp, insert the slope compensation resistor,  $R_{\text{RAMP}}$ , between CS and  $R_{\text{SENSE}}$ .

The CS current limit,  $V_{\text{CSLIM}}$ , is internally set to 120 mV. Calculate the  $R_{\text{SENSE}}$  value by

$$R_{\text{SENSE}} = \frac{V_{\text{CSLIM}} - R_{\text{RAMP}} \times 20 \; \mu\text{A}}{I_{\text{PKPRI}}}$$

where:

 $V_{CSLIM}$  is the CS current limit.

 $I_{PKPRI}$  is the primary peak current.

When the sensed input peak current is above the CS limit threshold, the controller operates in the cycle-by-cycle constant current-limit mode for 1.5 ms. Then the controller immediately shuts down the primary and secondary drivers. The controller then goes into hiccup mode for the next 40 ms and restarts the soft start sequence after this timeout period.

The slope ramp can affect the accuracy of the current-limit threshold because the voltage drop across  $R_{\text{RAMP}}$  contributes to

the inaccuracy of the peak current limit. For instance, if the added slope ramp voltage is 20% of the current-limit threshold, the actual input peak current limit can be off by as much as 20% depending on where the peak current-limit threshold is tripped during the on cycle. In the event of an output short circuit, the controller treats this condition as an overcurrent event and enters the 40 ms hiccup mode.

Under certain conditions, the ADP1074 exits OCP hiccup mode. In these conditions, the COMP pin is at the maximum clamp level, but the device does not enter hiccup mode. However, it is guaranteed that the PWMs are terminated whenever the CS maximum threshold is reached. The condition under which the ADP1074 skips entering hiccup mode is when VDD2 is powered through an auxiliary winding and an output short circuit occurs that results in the FB pin having a voltage that is <300 mV. This event is more prominent at high temperatures (>85°C), and can be exacerbated at higher temperatures.

The root cause of the device exiting hiccup mode is due to the effect that the OCP hiccup mode feature has on the SS2 pin. During OCP recovery, the SS2 pin tracks the FB pin and attempts a soft start from the precharge sequence. During the time when SS2 tracks the FB pin, the SS2 pin voltage can be less than the FB pin for a short interval, which causes the COMP pin (output of the gm amplifier) to momentarily dip below the maximum COMP pin clamp level. This event means that the current limit required for the next few switching periods is less than the maximum threshold and puts the device out of hiccup mode because the ADP1074 fails to register 1.25 ms worth of consecutive overcurrent cycles.

The following scenarios guarantee OCP hiccup mode based on the configuration of the VDD2 power supply:

- When VDD2 is powered directly from the output voltage, if a short circuit occurs on the output terminals of the load after steady state regulation is achieved, the voltage of the VDD2 pin is less than the UVLO, and the device enters hiccup mode for 200 ms, similar to the hiccup time described in the Remote System Reset section.
- 2. When VDD2 is powered through auxiliary winding or another configuration, when a short circuit occurs on the output terminals, the auxiliary winding is not shorted and maintains a positive voltage above the UVLO threshold of the VDD2 pin. To enter hiccup mode, it is recommended to use the circuit shown in Figure 15. The circuit operates as follows: when the output voltage goes low due to a short circuit, the D1 diode turns on, which pulls the base of the bipolar junction transistor low, shutting off VDD2. The system then enters hiccup mode, as described in the Remote System Reset section.

R3 is sized to bias the Zener diode and R4 is sized such that  $(V_{ZENER} - 1)/R4 > I_{ZENER}$ , where  $V_{ZENER}$  is the voltage of the diode and IZENER is the biasing current of the diode. This sizing ensures that the impedance of the resistor is less than the impedance of the diode, which causes the voltage of the diode to drop, and allows VDD2 to enter UVLO. If the output voltage is <5 V, the same procedure can be used to size the R4 resistor. If a discrete LDO is not used, a simple resistor and diode connector to the output voltage is sufficient. In this case, the R4 resistor is sized to limit the current through the D1 diode when the output voltage is 0 V during a short-circuit event. Because the bandwidth of the system is high, the ADP1074 is able to maintain voltage regulation at the proper voltage level, even if the auxiliary winding voltage is higher than the output voltage. The soft start and soft start from precharge conditions is met with the addition of this circuit due to the bandwidth of the overall system.

Figure 15. Recommended Circuit to Guarantee Hiccup Mode Showing Typical Values

# **TEMPERATURE SENSING**

The ADP1074 has an internal temperature sensor that shuts down the controller when the internal temperature exceeds the OTP limit. At this time, the primary and secondary MOSFET drivers (PGATE, NGATE, SR1, and SR2) are held low. When the temperature drops below the OTP hysteresis level, the ADP1074 restarts with a soft start sequence.

# **FREQUENCY SETTING (RT PIN)**

The switching frequency can be programmed in a range of 50 kHz to 600 kHz by connecting a resistor from RT to AGND1. A small current flows out of the RT pin and the voltage across it sets up the internal oscillator frequency. The value of this pin is approximately 1.224 V in steady state. Use the following equation to determine the resistor (in  $\Omega$ ) for a particular switching frequency (in kHz):

$$f_S(\text{kHz}) = \frac{1}{41.67 \times 10^{-12} \times (R_{TOP} + R_{POT})} \times \frac{1}{1000}$$

where:

*f*<sub>S</sub> is the switching frequency.

 $R_{TOP}$  is the top resistor of the divider.

 $R_{BOT}$  is the bottom resistor of the divider.

#### **MAXIMUM DUTY CYCLE**

To prevent the transformer core from saturating in the event of high current or extreme load transient and reduce voltage stress on the MOSFETs, a maximum duty cycle clamp can be set by connecting the DMAX pin to the center tap of the resistive divider that is connected from RT to AGND1, as shown in Figure 16.

Figure 16. Setting the Maximum Duty Cycle, D<sub>MAX</sub>

The maximum duty cycle is calculated by the following:

$$D_{MAX} = 50 + \frac{50 \times R_{BOT}}{(R_{TOP} + R_{BOT})} \%$$

where:

 $D_{MAX}$  is 50% when  $R_{BOT}$  is 0  $\Omega$  or when the DMAX pin is connected to AGND1. For example, when  $R_{TOP}$  is equal to  $R_{BOT}$ ,  $D_{MAX}$  is 75%.  $D_{MAX}$  can reach 100% if  $R_{TOP}$  is 0 or when  $R_{BOT}$  becomes open circuit.

 $R_{BOT}$  is the bottom resistor of the divider.

 $R_{TOP}$  is the top resistor of the divider.

As an added protection feature to prevent open-loop conditions, the maximum duty cycle is also applicable during soft start. If the controller reaches DMAX during soft start for three consecutive switching periods, the 40 ms hiccup timer is initiated.

#### FREQUENCY SYNCHRONIZATION

The switching frequency of the ADP1074 can be synchronized to an external clock at the SYNC pin. When an external clock rising edge is first detected, it takes approximately seven to ten periods for the internal clock to lock in the SYNC clock frequency. In between the time that the SYNC clock is detected and the time that it is locked in, the controller continues to operate with the internal oscillator frequency.

The SYNC frequency must be within  $\pm 10\%$  of the internal oscillator frequency set by the RT pin; otherwise, synchronization does not take place.

A clock signal can be applied to SYNC on the fly or prior to the soft start sequence. A dithered clock can also be applied to SYNC to reduce the peak electromagnetic interference (EMI) noise in the converter output and switch node. The internal clock is able to lock onto the dithered clock cycle by cycle.

It is recommended to connect the SYNC pin to AGND1 if this feature is not used.

# **SYNCHRONOUS RECTIFIER (SR) DRIVERS**

There are two synchronous rectifier drivers on the secondary side for driving the synchronous switches. SR1 is the forward driver that is in phase with the primary side NGATE driver, and SR2 is the freewheeling driver. VDD2 is the front end of the LDO at VREG2. The 5 V internal LDO at VREG2 powers the SRx drivers and all internal circuits on the secondary side. The recommended power supply range at VDD2 is from 6 V to 36 V. However, at 36 V input to VDD2, the power dissipation in the LDO can be significant. If VDD2 is less than 5 V, the LDO operates in the dropout region, where VREG2 and the driver output are less than 5 V. In this case, it is recommended to supply VDD2 with an auxiliary power supply greater than 5 V.

VDD2 can be directly connected to the converter output or an auxiliary power supply, which can be realized by using a third winding of the main transformer. For additional drive strength, SR1 and SR2 can be fed into an external MOSFET driver such as the ADP3624 or the ADP3654.

# **OUTPUT OVERVOLTAGE PROTECTION (OVP)**

When the output voltage exceeds the OVP threshold of 1.36 V, the controller immediately shuts off the drivers (NGATE, PGATE, SR1, and SR2) on both the primary and secondary side. When the voltage at the OVP drops below the OV hysteresis level, the controller resumes switching in the next switching period with the primary drivers, followed by phasing in of the SR1 and SR2 PWMs. The OVP feature causes the system to enter hiccup for 200 ms if the voltage on the OVP pin exceeds 1.36 V for a sustained period of 200  $\mu s$ .

# **ACTIVE CLAMP (PGATE)**

In a forward converter, the magnetizing energy stored in the transformer core during the on cycle must be demagnetized or reset during the off cycle; otherwise, the transformer core saturates in subsequent switching cycles. To reset the transformer core, an active clamp switch is turned on during the off cycle, which enables the reset of the transformer. This process reduces power dissipation and increases overall efficiency. The active clamp switch can be a high-side or a low-side switch using the driver at the PGATE pin.

#### LEADING EDGE BLANKING

A leading edge blanking time is added after the rising edge of the NGATE signal to avoid picking up any unwanted noise or ringing at the CS pin at the start of the switching period.

# **GATE DELAY AND SR DEAD TIME**

At high input voltages, the rise and fall times of the main MOSFET on the primary side are larger than at lower input voltages. It is important to have a programmable delay time between the PGATE rising and the NGATE rising to account for different input voltages, leakage inductances of the transformer, and MOSFET output capacitances. Also, a sufficient gate delay between PGATE and NGATE ensures zero volt switching (ZVS), which

is important for reducing switching losses in the main MOSFET.

The total delay between the PGATE and NGATE rising edges can be programmed with a resistor connected to the NGATE pin. The resistor connected to NGATE is determined by the ADP1074 prior to soft start. The programmable delay between PGATE to NGATE has four discrete settings having typical values of 30 ns, 60 ns, 100 ns, and 150 ns. See Figure 17 for more details.

Figure 17. Gate Delay and SR Dead Time Settings

To maximize efficiency and avoid cross conduction between the primary NGATE and SR2 (freewheeling switch), it is necessary to have a delay time between SR2 and NGATE.

As shown in Figure 17, the NGATE falling edge and SR1 falling edge turn off simultaneously with an *i*Coupler delay.

In addition, a dead time between SR1 and SR2 is internally fixed to 25 ns (typical) to avoid shorting out the secondary transformer winding.

# LIGHT LOAD MODE (LLM) AND SR PHASE IN

Add a resistor at the MODE pin to enable the ADP1074 power saving LLM feature. A current source from the MODE pin of 6.5  $\mu A$  into this resistor sets up the LLM threshold voltage, which is compared to the COMP voltage. When the COMP voltage rises above the LLM threshold (that is, the MODE pin voltage), the SRx PWMs gradually increase (or phase in) from the duty cycle at light load to the steady state duty cycle at the SRx phase in rate. The SRx phase in rate moves the SRx edges every 1.5 ns per  $\mu s$ . Without the phase in sequence, a dip in the output voltage can occur if the SRx PWMs transition from zero to full duty cycle instantaneously.

In a load dump situation, for example, when the load is stepped from full load to light load, that is, from continuous conduction mode (CCM) to discontinuous conduction mode (DCM) operation, the duty cycles of the SRx PWMs gradually phase out at the SRx phase out rate, which has the same numerical value of the SRx phase in rate. The phase out sequence of the SRx PWMs prevents reverse current in the secondary, and at the same time, optimizes the dynamic performance of the output response. Note that the level of COMP is still above the minimum COMP clamp level at this point, and the ADP1074 outputs duty cycles with minimum on time.

If the load is further reduced and the COMP pin voltage becomes equal to the minimum COMP clamp level, the ADP1074 enters pulse skip mode.

The NGATE delay time settings shown in Figure 17 remain unchanged in LLM operation. Use the following formula to set up the light load mode threshold:

$$R_{MODE} = \frac{I_{PEAK\_LLM} \times CS_{GAIN} + 0.8}{I_{MODE}}$$

where:

 $I_{PEAK\_LLM}$  is the peak primary current at the light load condition.  $CS_{GAIN} = 12.5$ .

 $I_{MODE}$  is the current flowing out of the MODE pin.

For a forced CCM operation, connect MODE to AGND2. In this case, pulse skipping is disabled.

Note also that when the system enters light load mode, the synchronous rectifiers terminate at the falling edge of SR1. This termination facilitates the prevention of the PWM at a negative current, which can cause a spike in voltage that can damage the synchronous FET.

# **EXTERNAL START-UP CIRCUIT**

For input voltages higher than 36 V, where the power dissipation in the internal 8 V LDO can be significant, the use of an external start-up circuit is recommended. (See Figure 18 for an example.) In this case, the VIN and VREG1 pins are shorted together and connect to the output of the start-up circuit. Because the input pre-enable bias current, the (VIN + VREG1) start-up current, is approximately 160  $\mu\text{A}$ , the output of the start-up circuit must be able to provide this level of current to perform a soft start. The auxiliary winding then provides the bias voltage, shutting off the start-up circuit after soft start completes.

Figure 18. Precision EN Circuit Connection with an External Start-Up Circuit

A fast start-up circuit is shown in Figure 19. This circuit requires two components: a Zener diode, which sets up the start-up voltage at the VIN and VREG1 pin, and a negative-positive-negative (NPN) transistor, which sets up a fast current path for charging up the start-up capacitor, C1. The start-up current through R1 must be more than 160  $\mu$ A, which is the minimum specified start-up current, and it is recommended that the start-up voltage at VREG1 and VIN be approximately 8 V to 13 V.

The auxiliary winding then provides the bias voltage, shutting off the NPN transistor after soft start completes.

Figure 19. Fast Start-Up Circuit

# **SOFT STOP**

The ADP1074 employs a soft stop feature that brings the output voltage gradually down to zero by using the SS2 pin as a reference. During the soft stop procedure, the SS2 pin is discharged to zero by a current sink of approximately 1.5 times the value during closed-loop soft start.

When the voltage at EN drops below the EN threshold, the SR1 and SR2 secondary drivers shut off immediately, and the primary NGATE pulse width gradually decreases the duty cycle from the last known condition to the minimum pulse width and down to zero, causing the output voltage to decrease. The soft stop feature prevents any reverse current when the controller is shut down.

When the output voltage decreases below the VDD2 UVLO threshold, there is no transmission of the COMP signal to the primary side. Therefore, the output voltage continues to decrease at the rate at which the load current discharges the output capacitor.

When the load is at a minimum or at no load, the output voltage does not discharge because any reduction in duty cycle or current limit does not discharge the output voltage linearly.

# **POWER GOOD**

The  $\overline{PGOOD}$  pin is an open-drain N-channel metal-oxide semiconductor (nMOS), which is off in fault conditions. Connect a pull-up resistor between  $\overline{PGOOD}$  and VREG2 or to an external power supply less than 5.5 V.

To toggle PGOOD, the fault voltage on the FB pin and the OVP pin must exceed the overvoltage threshold of 1.36 V. PGOOD also toggles if the FB pin voltage drops 100 mV below the nominal of 1.2 V, that is, to 1.1 V.

PGOOD toggles again after the output voltage crosses the PGOOD hysteresis voltage of 36 mV. PGOOD becomes active after a delay of 5 μs for an FB pin fault and after 90 ns for an OVP pin fault.

#### OCP/FEEDBACK RECOVERY

During steady state, the FB pin is at 1.2 V. At this time, the SS2 pin voltage is 1.4 V. Under abnormal situations, such as an overload condition, the output voltage can dip severely. In such an event, the current limit is at the maximum level, and the COMP pin voltage is at its clamp level. If the two conditions of the COMP pin voltage being clamped and  $V_{\text{FB}} < (1.2 \, \text{V} - 100 \, \text{mV})$  are satisfied, the controller discharges the SS2 pin using a fast current sink (200  $\mu A)$  to make the SS2 pin equal to the FB pin. The controller then attempts to perform a soft start from this precharged condition, that is, from the last known value of the output voltage. This process is how the OCP/feedback recovery feature operates.

However, if at any time the voltage on the COMP pin is above the maximum clamp voltage for a period greater than 1.5 ms, the system enters hiccup mode.

During the soft start from precharge, the output voltage rises at the same rate as determined by the capacitor on the SS2 pin. If, however, there is a detrimental fault in the power stage that prevents the rise of the output voltage,  $V_{FB}$  does not track SS2, and when SS2 > ( $V_{FB}$  + 100 mV), the COMP pin voltage increases to the clamp level, and the system again enters OCP/feedback recovery mode.

#### **OUTPUT VOLTAGE TRACKING**

The ADP1074 offers a tracking feature. During steady state, the FB pin is at 1.2 V. At this time, the SS2 pin voltage is at 1.4 V. Using an external DAC, the voltage on the SS2 pin can modulate the output voltage. It is recommended that the SS2 pin voltage be changed only after the VDD2 UVLO point is crossed, and control is handed over to the secondary side, or else the handover process does not occur smoothly, resulting in glitches in the output voltage. Ideally, the  $\overline{PGOOD}$  pin can be used as a signal that indicates that regulation is achieved, to initiate the tracking.

The SS2 voltage must be brought down from 1.4 V to 1.2 V, and it must be brought down even further to effect any change in the output voltage. The rate at which the output tracks the SS2 pin is dependent upon the overall system bandwidth. Note that while modulating the output voltage, if the  $\overline{FB}$  pin voltage drops below (1.2 V - 100 mV = 1.1 V), the  $\overline{PGOOD}$  pin toggles.

# **REMOTE SYSTEM RESET**

For a remote (secondary side) system shutdown, an open-drain general-purpose input/output (GPIO) of an external microcontroller can be used to force the SS2 pin to 0 V. This pull-down causes the ADP1074 to regulate to 0 V, and the ADP1074 enters pulse skip mode or outputs a minimum duty cycle because the SS2 pin offsets because of the finite resistance of the GPIO.

When VDD2 is charged from the output bus, this setup is equivalent to a system shutdown, because when VDD2 < VDD2 UVLO, the ADP1074 enters a special hiccup mode of 200 ms (instead of the standard 40 ms hiccup).

When VDD2 is powered using auxiliary winding, the system regulates to the voltage proportional to the voltage on the SS2 pin and eventually enters the special hiccup mode previously mentioned, after the auxiliary rail decays below the VDD2 UVLO threshold.

Therefore, the SS2 pin can achieve output tracking as well as a secondary side shutdown, also known as remote system reset, as shown in Figure 20.

Figure 20. Remote Software Reset with 200 ms Hiccup

Figure 21. Tracking with SS2 Pin

#### **OCP COUNTER**

During overload conditions, when the peak sensed currents exceed the OCP threshold voltage of 120 mV on the CS pin, the ADP1074 immediately terminates the remainder of the PWM pulse. If the peak sense current continues to exceed the threshold every switching period for 1.5 ms, the system enters hiccup mode, by which it shuts down for approximately 40 ms and then soft starts. During an exceeded overcurrent situation, such as a dead short, it is likely that the programmed slope compensation is not enough, and therefore, the system enters subharmonic oscillation. If this is the case, the system cannot enter hiccup mode because the OCP threshold is crossed every alternate switching period, and the 1.5 ms hiccup counter resets.

To prevent this scenario, the ADP1074 latches the last known state, whereby if an OCP condition registered as a 1 in one switching period and as a 0 in the next switching period, it is still counted as a 1. In this manner, the system can enter hiccup mode even in subharmonic oscillation. Missing two OCP thresholds consecutively resets the hiccup counter.

# **INSULATION LIFETIME**

All insulation structures eventually break down when subjected to voltage stress over a sufficiently long period. The rate of insulation degradation is dependent upon the characteristics of the voltage waveform applied across the insulation. In addition to the testing performed by the regulatory agencies, Analog Devices carries out an extensive set of evaluations to determine the lifetime of the insulation structure within the ADP1074.

Analog Devices performs accelerated life testing using voltage levels higher than the rated continuous working voltage. Acceleration factors for several operating conditions are determined. These factors allow calculation of the time to failure at the actual working voltage.

The values shown in Table 10 summarize the peak voltage for 50 years of service life for a bipolar ac operating condition. In many cases, the approved working voltage is higher than the 50 year service life voltage. Operation at these high working voltages can lead to shortened insulation life in some cases.

The ADP1074 insulation lifetime depends on the voltage waveform type imposed across the isolation barrier. The *i*Coupler insulation structure degrades at different rates depending on whether the waveform is bipolar ac, unipolar ac, or dc. Figure 22, Figure 23, and Figure 24 show these different isolation voltage waveforms.

A bipolar ac voltage environment is the worst case for the *i*Coupler products, yet meets the 50 year operating lifetime recommended by Analog Devices for maximum working voltage. In the case of unipolar ac or dc voltage, the stress on the insulation is significantly lower. The low stress allows operation at higher working voltages while still achieving a 50 year service life. Treat any cross insulation voltage waveform that does not conform to Figure 23 or Figure 24 as a bipolar ac waveform, and limit its peak voltage to the 50 year lifetime voltage value listed in Table 10.

Note that the voltage presented in Figure 23 is shown as sinusoidal for illustration purposes only. It is meant to represent any voltage waveform varying between 0 V and some limiting value. The limiting value can be positive or negative, but the voltage cannot cross 0 V.

# **LAYOUT GUIDELINES**

The layout guidelines for the primary side are as follows:

- Ground all the capacitors to their respective grounds. For example, ground the SS1 capacitor to AGND1.
- Use the CS pin and the AGND1 pin to differentially sense the primary current measurement through the sense resistor. Do not cross the CS and AGND1 traces for current sensing across any switch nodes.
- 3. Place a capacitor (33 pF to 470 pF typical) close to the CS pin, connected to AGND1.
- 4. Connect the ground plane on the primary side to PGND1.
- 5. Connect AGND1 to PGND1 using a 0  $\Omega$  resistor.
- 6. Place resistors (1  $\Omega$  to 5  $\Omega$  typical) in series with NGATE and the main power MOSFET. These resistors aid in eliminating any ringing on the drive voltages.

The layout guidelines for the secondary side are as follows:

- 1. Ground all the capacitors to their respective grounds. For example, ground the SS2 capacitor to AGND2.
- 2. Place resistors (1  $\Omega$  to 5  $\Omega$ ) in series with SRx and the synchronous MOSFET. These resistors aid in eliminating any ringing on the drive voltages.
- 3. Connect the ground plane on the secondary side to PGND2. Connect the negative terminal of the output voltage to the PGND2 plane.
- 4. Use the FB pin and the AGND2 pin to remotely differentially sense the output voltage by connecting AGND2 to the negative terminal of the output voltage using a 0  $\Omega$  resistor.
- 5. Use a 100 nF capacitor on the MODE pin if light load mode is used in noisy environments.

**NOTES**
